Abstract

Introduction: The 6-minute walk test (6 MWT) distance is frequently used in the prediction of pulmonary hypertension (PH) prognosis. However, potential surrogates of this measure have not been established. We aim to describe the clinical, echocardiographic, and laboratorial criteria determining the 6 MWT distance in patients with PH.

Methods: In 22 consecutive PH patients, functional capacity was evaluated by the 6 MWT distance and compared with levels of neurohormonal activation biomarkers and echocardiographic parameters for right ventricular (RV) function.

Results: A correlation between the 6 MWT distance and several clinical parameters was found: Borg's pre-test classification ($R=-0.46$; $p=0.038$); WHO functional class ($p=0.029$). Patients with higher levels of aldosterone ($R=-0.46$; $p=0.030$), renin ($R=-0.43$; $p=0.046$) and mid-regional pro-adrenomedullin (MR-proADM, $R=-0.53$; $p=0.009$) had worse 6 MWT performance. The opposite was true for natremia levels ($R=0.55$; $p=0.006$). There was a positive correlation between the 6 MWT distance and RV global longitudinal peak systolic strain rate and early diastolic strain rate ($R=0.49$; $p=0.038$ and $R=-0.55$; $p=0.018$, respectively). On multivariate analysis, only natremia and early diastolic strain rate were predictors of the 6 MWT distance.

Conclusion: The 6 MWT distance correlated with renin-angiotensin-aldosterone system activation and parameters for RV myocardial deformation. The new biomarker MR-proADM proved to be useful in the prediction of the functional capacity.

Introduction

Pulmonary hypertension (PH) is defined as an increase in mean pulmonary arterial pressure ≥ 25 mmHg at rest as assessed by right heart catheterization [1]. The prognosis of patients with PAH has improved with modern therapies, but patient outcomes overall remain poor [2,3]. Identification of prognostic markers (clinical, laboratorial and genetic) to early find high risk subgroups is crucial.

In the recent years, in addition to a better understanding of the pathophysiological mechanisms underlying PH, there has been significant development of methods and interventions with diagnostic and prognostic relevance addressing this disease, with a particular interest in biomarkers. Since there is no single variable that provides sufficient diagnostic and prognostic information, a comprehensive assessment and multidimensional approach is required. In patients with PH, the 6-min walk test (6 MWT) distance provides an assessment of exercise capacity. Because limited functional capacity profoundly influences the clinical status, changes in 6 MWT distance have been employed as an endpoint in clinical studies conducted for regulatory approval in patients with PH of different etiologies [4,5]. A 15% decrease in the 6 MWT distance coupled with other clinical markers suggesting deterioration or escalation of medical therapy has been included in definitions of "time to clinical worsening" end points [1].

Anthropometric factors, physical activity, chronic illness and motivation are known to influence the 6 MWT distance [1]. However, the predictive value of some parameters that have been utilized as endpoints in overall functional capacity, reflecting PH severity, is not well established. Therefore, we aim to establish clinical, echocardiographic and laboratorial parameters associated with 6 MWT distance and relevant to further prognostic assessment, and to better define mechanisms underlying functional changes together with their value as markers of disease modification in PH.

Methods

Study design

We carried out a prospective cohort study of 22 consecutive PH patients followed in PH clinic. Inclusion criteria comprised the presence of symptomatic (WHO functional class II-IV) PH types I and IV (clinical classification [1]). PH was defined as mean pulmonary artery pressure ≥ 25 mmHg, assessed by right heart catheterization. Patients were excluded if they had a history of surgery or major trauma in the two months prior to inclusion, active neoplastic disease, liver cirrhosis or myocardial infarction. All patients were treated according to the European Society of Cardiology/European Respiratory Society (ESC/ERS) recommendations [4]. The study was approved by local ethics committee.

Patients underwent clinical assessment with WHO functional class and Borg Scale for Perceived Dyspnea along with echocardiographic evaluation and exercise capacity assessment through 6 MWT.

Biochemical analyses

Several biomarkers were determined: uric acid, amino-terminal pro-brain natriuretic peptide (NT-proBNP), troponin I, mid-regional pro-adrenomedullin (MR-proADM) and aldosterone.

EDTA-plasma samples were collected from an antecubital vein after 5 minutes of rest. Complete blood and platelet counts, serum creatinine, sodium, urea, uric acid, troponin I, NT-proBNP, aldosterone and renin were processed and analyzed in the hospital laboratory. NT-proBNP levels were determined on solid phase immunometric assay Immulite 2000 (Siemens Healthcare Global®, Breda, The Netherlands), commercially available and validated in the clinic. Blood osmolality was calculated using the following formula: $\text{osmolality} = 1.86 \times [\text{sodium (mmol/L)}] + [\text{glucose (mg/dL)}]/18 + [\text{Urea (mg/dL)}]/5992 + 9$. Aliquots of plasma samples were stored at -80°C for further analysis.

Echocardiography

A GE Vivid 7 Dimension® echocardiography machine was used. Digital images were post-processed in EchoPAC Dimension software (GE Healthcare®, Milwaukee, WI). All patients underwent a complete transthoracic echocardiogram, performed according to the recommendations of the American Society of Echocardiography [6-8]. Standard two-dimensional echocardiographic evaluation of left ventricular (LV) and right ventricular (RV) size and function was performed. The following indices were obtained from the apical 4-chamber view: RV basal end-diastolic dimension; RV fractional area change $[(\text{RV end-diastolic area} - \text{RV end-systolic area})/\text{RV end-diastolic area}]$; and maximal tricuspid annular plane systolic excursion (TAPSE). RV wall thickness was measured from the subcostal view. The peak tricuspid regurgitation velocity, recorded by continuous wave Doppler echocardiography, was selected from multiple standard views and the values from 3 consecutive beats were averaged. The pulmonary artery systolic pressure was calculated as the sum of the peak systolic tricuspid pressure gradient (calculated by modified Bernoulli equation from peak tricuspid regurgitation velocity) and estimated right atrial pressure (according to inferior vena cava size and respiratory kinetics).

Colour-coded tissue Doppler images of the RV free wall were obtained from the apical 4-chamber view ensuring a frame rate of >100 frames/s. Speckle-tracking analysis was used to generate regional myocardial strain and displacement. RV longitudinal strain was assessed in apical four-chamber views. Myocardial deformation was expressed as the percentage change from the original dimension at end-diastole. Myocardial lengthening was represented as a positive value and myocardial shortening was represented as a negative value. Values obtained in the basal and mid-ventricular segments were averaged together to obtain the following measurements: RV peak global longitudinal systolic strain; RV peak global longitudinal systolic strain rate (GLSRs); RV peak global longitudinal early diastolic strain rate (GLSRe); RV peak global longitudinal end-diastolic strain rate (GLSRa).

Statistical analysis

Continuous variables were presented as median and inter-quartile range. Categorical variables were presented as a number and percentage. The differences between these variables were calculated using the chi-square test. The multivariate model was based on an algorithm using all biomarkers tested.

Correlations between MR-proADM and other variables were explored using Pearson's test. A p-value ≤ 0.05 was considered significant in all tests. The statistical software IBM SPSS Statistics® version 20.0 (IBM GmbH, Ehningen, Germany) was used.

Results

Detailed clinical, laboratorial and echocardiographic characteristics of the 22 patients are described in Table 1. The median age was 60.0

Variables*	Global (n=22)

Table 1: Baseline clinical, laboratorial and echocardiographic characteristics.

(IQR, 43.0 to 67.5) years-old. The majority of patients were female (68%, n=15). Etiologic investigation disclosed inoperable chronic thromboembolic disease as the cause of PH in 5 patients (23%). The remaining 17 patients had etiologies that met Group I (Nice criteria 2013). All patients were symptomatic, with 73% having WHO class II symptoms.

A negative correlation was seen between the 6 MWT distance and WHO functional class ($S=-0.48$, $p=0.021$) and the pretest Borg scale ($S=-0.52$, $p=0.017$), as shown in Figures 1 and 2, respectively. The 6 MWT distance also correlated with some laboratorial parameters: directly with sodium level ($R=0.55$, $p=0.006$) and inversely with serum aldosterone ($R=-0.46$, $p=0.030$), renin ($R=-0.43$, $p=0.046$) and MR-proADM ($R=-0.53$, $p=0.009$) (Figures 3, 4, 5 and 6, respectively).

There was no statistically significant relationship between the 6 MWT distance and serum levels of NT-proBNP and uric acid.

The only echocardiographic variables that correlated with the 6 MWT distance were GLSRs ($R=0.49$, $p=0.038$) and GLSRe ($R=-0.55$, $p=0.018$) (Figures 7 and 8, respectively). The conventional parameters of the RV function did not show any statistically significant association.

Discussion

In the present study, we sought to determine the power of several clinical, laboratorial and echocardiographic variables in predicting the 6 MWT results in patients with PH. We hypothesized that the 6 MWT distance correlated with neurohumoral and echocardiographic parameters reflecting PH severity.

This study demonstrated that serum concentration of aldosterone, renin, MR-proADM and sodium, in addition to right ventricle strain imaging parameters, correlated with 6 MWT distance.

Figure 5: Correlation between 6 MWT distance and renin in 22 PH patients (at inclusion). The linear regression line is superimposed, surrounded with the 95% confidence interval lines for the regression line. r =Pearson correlation coefficient. p = p value.

Figure 6: Correlation between 6 MWT distance and MR-proADM in 22 PH patients (at inclusion). The linear regression line is superimposed, surrounded with the 95% confidence interval lines for the regression line. r =Pearson correlation coefficient. p = p value.

The successful use of the change in 6 MWT distance as a primary end-point in the pivotal PH trial of IV Epoprostenol [9] paved the way for its use as a primary end-point and indicator of symptom change in other trials for PH medications. It is the most widely used functional marker because it is derived from a simple test that correlates with hemodynamic variables and the results of cardiopulmonary exercise testing, as and it has prognostic value in the evaluation of PH patients [1,10,11]. By measuring the distance a patient can walk, the 6 MWT can indirectly quantify shortness of breath and fatigue, two of the most common symptoms of PH. However, PH is a chronic, progressive,

Figure 7: Correlation between 6 MWT distance and GLSRs in 22 PH patients (at inclusion). The linear regression line is superimposed, surrounded with the 95% confidence interval lines for the regression line. r =Pearson correlation coefficient. p = p value.

functionally debilitating disease, and the relevance of 6 MWT distance to long-term outcomes is questionable.

A correlation exists between increasing exercise capacity and the improvement of several peripheral abnormalities, in the absence of improvement in hemodynamic abnormalities in patients with cardiopulmonary disease [12]. It is possible that the changes that occur in the periphery as a consequence of the systemic effects of heart failure often become the exercise limiting factors more than the heart dysfunction that initiated the syndrome. The complexity of the question should raise the importance of a multi-parameter approach in the care of patients with PH, to help ensure that measures of functional capacity, clinical improvement or worsening and treatment effect are determined objectively.

In respect to biomarkers, a large number of neurohumoral peptides have shown superiority over those commonly used in heart failure and have the potential to be useful in monitoring PH. They offer the possibility of reducing the frequency of use of invasive tests and may be

particularly useful for screening, predicting the prognosis, monitoring and possibly assist in the selection of therapy of PH patients. However, to date only brain natriuretic peptide and NT-proBNP have been included as prognostic parameters in the guidelines [4]. The natriuretic peptide system is activated in chronic PH [13,14]. NT-proBNP levels have been related to hemodynamic and functional parameters [15,16], response to medical treatment [17] and mortality in patients with PH [18,19]. Neurohormonal activation of the sympathetic and renin-angiotensin-aldosterone system has been demonstrated in patients with PH, and occurs in proportion to the degree of RV dysfunction [20]. Systemic renin-angiotensin-aldosterone activity is increased in patients with PH and associated with disease progression. Due to increased angiotensin converter enzyme activity, pulmonary endothelial cells of patients with PH produce more angiotensin II, which in turn induces significant proliferation of pulmonary artery smooth muscle cell, RV afterload and pulmonary vascular remodeling [21]. Several studies have showed the importance of natremia in the evaluation of patients with PH. Forfia et al demonstrated that hyponatremia is associated with advanced right heart failure and reduced survival in patients with PH and predicted death even after adjusting for hemodynamic, echocardiographic and clinical variables of known prognostic importance in PH [22]. Our results suggested that natremia and neurohormonal activation biomarkers of the renin-angiotensin-aldosterone system correlate with functional capacity in patients with PH, likely reflecting differences in pulmonary and systemic hemodynamics. Of note, our patients were not treated with angiotensin converting enzyme inhibitors or angiotensin receptor blockers antagonists.

Plasma adrenomedullin is a potent hypotensive peptide that increases pulmonary blood flow. One study demonstrated that plasma adrenomedullin levels were increased in patients with pulmonary arterial hypertension compared with control subjects. Right atrial pressure, mean pulmonary arterial pressure, and pulmonary vascular resistance were highly correlated with adrenomedullin levels [23]. Our study is the first to show a correlation between MR-proADM levels and the 6 MWT results in PH. Patients with a worse performance on 6 MWT had higher levels of MR-proADM, which may be reflecting a compensatory mechanism regarding the vasodilatory properties of the peptide.

RV function is an important determinant of outcome in PH, however, its evaluation is challenging because of its geometry. Speckle-tracking strain echocardiographic evaluation is an easily obtained, angle-independent technique for quantifying myocardial deformation [24-27], including assessment of RV function in PH [28,29]. Sachdev et al. [30] showed that RV longitudinal systolic function by strain and strain rate independently predict future right-sided heart failure, clinical deterioration and mortality in patients with pulmonary arterial hypertension (PAH). An RV free wall strain below -12.5% in patients with PAH identified a cohort with marked RV dysfunction and predisposition to clinical deterioration.

In this study, we did not find a correlation between functional capacity (expressed by the 6 MWT distance) and RV global longitudinal systolic strain or TAPSE. However, it was found that patients with poor performance in the 6 MWT had higher RV global longitudinal systolic strain rate. Although the distinction between increased afterload or impaired contractility or both as the cause of deformation variability is difficult and may warrant further investigation, we propose that this finding may reflect adaptive changes of RV mechanics induced by PH.

Insight into the role of diastolic function in PH patients is scarce. In the past years, research has mainly focused on the influence of PH on

RV systolic function and the prognostic significance of this parameter [30]. There is evidence that RV diastolic function is impaired in PH patients. First, due to increased RV afterload, myocardial relaxation and filling may be impaired. Second, the RV compensatory hypertrophy in response to increased afterload reduces ventricular compliance and may impair diastolic function [31]. We found that GLSRe showed an inverted correlation with the 6 MWT distance, possibly reflecting some degree of diastolic dysfunction due to pressure overload and secondary remodeling.

We recognize several limitations of our study. The number of subjects included is small, but in low prevalence diseases such as PH amassing a large population of patients is rare even in a referral center. Patients were on variable therapies at inclusion. In this regard, recent meta-analysis of PH trials have consistently shown that while baseline 6 MWT distance strongly predicts survival, changes in 6 MWT distance in response to specific therapies did not predict disease outcomes [11,32]. Furthermore, there are intrinsic limitations of speckle-tracking strain echocardiography including relatively low reproducibility with suboptimal intra- and interobserver variabilities, broad ranges of normal values due to patient-to-patient variability, dependence on image quality and frame rate and image resolution.

Conclusion

In conclusion, the 6 MWT distance correlated with the activation of the renin-angiotensin-aldosterone system and parameters of RV myocardial deformation. The MR-proADM levels proved to be useful in the prediction of the functional capacity.
